# Supply Chain Monitoring and Child Labor: Evidence from Bangladesh Following Rana Plaza

Alina Malkova Clara Canon

Florida Institute of Technology

March 2026

**Abstract**

This paper examines whether supply chain monitoring reduces child labor in developing countries, exploiting the 2013 Rana Plaza disaster as a quasi-experimental shock to factory oversight in Bangladesh. Using geocoded household survey data for 100,473 children linked to factory locations via cluster-level GPS coordinates, we employ a difference-in-differences strategy comparing areas within 10km of textile factories to more distant locations. We find a precisely estimated null effect on child labor ($-0.6$ pp, $p = 0.46$); equivalence testing formally rejects effects larger than $\pm 2$ pp ($p = 0.03$). The null is robust across trend-adjusted specifications, matching methods, triple-difference designs, and continuous treatment measures. However, subgroup analysis reveals meaningful heterogeneity: girls near monitored factories experience a significant 3.25 pp increase in school enrollment ($p = 0.012$), with no corresponding effect for boys (triple interaction $p = 0.004$). Middle-wealth households show enrollment gains of 5–6 pp ($p < 0.01$). Lee (2009) bounds confirm these results are robust to selective attrition. A decomposition reveals that child labor is concentrated in agriculture and the informal sector, outside the scope of factory audits. These findings demonstrate that factory monitoring alone does not reduce child labor but may generate positive educational spillovers, particularly for girls and middle-income households.

# 1 Introduction

The persistence of child labor in global supply chains affects an estimated 160 million children worldwide (ILO, 2021). While theoretical models predict ambiguous effects of trade integration on child labor (Edmonds and Pavcnik, 2005; Basu and Van, 1998; Baland and Robinson, 2000), empirical evidence on the effectiveness of supply chain interventions remains limited (Edmonds, 2020). This paper examines how intensified factory monitoring following the 2013 Rana Plaza disaster affected child labor in Bangladesh.

The collapse of the Rana Plaza factory complex on April 24, 2013—killing 1,134 workers—triggered unprecedented monitoring through the Bangladesh Accord and Alliance for Worker Safety, collectively covering over 2,000 factories (Labowitz and Baumann-Pauly, 2015; Donaghey and Teague, 2014). These programs mandated third-party inspections with age verification requirements, providing a plausibly exogenous shock to oversight since the disaster resulted from structural failures unrelated to child labor (Kabeer et al., 2019).

We use five waves of the Bangladesh DHS (2000–2014) with GPS-coded data on children, linked to geocoded factory locations. Our difference-in-differences strategy compares child labor outcomes for households within 10 kilometers of textile factories to those in more distant areas, before and after Rana Plaza (Heath and Mobarak, 2018; Blum et al., 2023).

Using cluster-level GPS coordinates from DHS surveys—rather than coarser division-level geographic data—we find no statistically significant effect of post-Rana Plaza factory monitoring on child labor. Point estimates for children aged 10–13 are small ($-0.56$ percentage points, $p = 0.46$) and statistically insignificant across all specifications. Unlike preliminary analyses that used division-capital coordinates and found spurious pre-trends and significant treatment effects, the corrected cluster-level GPS data reveals no differential pre-trends ($+0.02$ pp/year, $p = 0.93$) and null treatment effects that are stable across trend-adjusted specifications, matching methods, triple-difference designs, and sensitivity analysis following Rambachan and Roth (2023).

These null findings contribute to an emerging literature questioning the effectiveness of private governance in reducing child labor in developing countries (Locke et al., 2007; Distelhorst and Locke, 2018). Our results also highlight the critical importance of geographic data quality in spatial quasi-experiments: the use of division-capital coordinates rather than cluster-level GPS produced entirely different (and misleading) results. This underscores the need for careful data validation in difference-in-differences designs that rely on geographic variation in treatment exposure.

The remainder of this paper proceeds as follows. Section 2 reviews the relevant literature. Section 3 describes the institutional context. Section 4 details our data sources. Section 5

develops the empirical strategy. Section 6 presents the main results and robustness analysis. Section 7 discusses interpretations and limitations. Section 8 concludes.

# 2 Related Literature and Theoretical Framework

## 2.1 Theoretical Foundations of Child Labor Supply and Demand

Our analysis builds on the theoretical framework established by Basu and Van (1998), who formalized the "luxury axiom" whereby households supply child labor only when adult earnings fall below subsistence levels, and the "substitution axiom" whereby child and adult labor are substitutes in production. These assumptions generate multiple equilibria with potential poverty traps, where regulatory interventions may shift economies between child labor and non-child labor equilibria Basu and Tzannatos (2000); Doepke and Zilibotti (2005).

Recent theoretical extensions particularly relevant to our context include Edmonds (2007b), who models how trade liberalization affects child labor through both income and substitution effects, and Dumas (2020), who incorporates human capital dynamics and shows how temporary interventions can have permanent effects through education investments. The framework in Baland and Robinson (2000) demonstrates how credit constraints create inefficient child labor even when parents are altruistic, suggesting financial market development as a complementary intervention—a mechanism we test by examining heterogeneity across areas with differential bank branch density.

Our null empirical findings are informative for this theoretical literature. The absence of detectable effects at any age—including the factory-relevant ages of 10–13—suggests that either monitoring does not produce community-level spillovers in child labor, or that the effects are too localized to detect in household surveys. This is consistent with models where child labor is driven primarily by household poverty and agricultural demand rather than factory employment opportunities (Edmonds, 2007).

## 2.2 Empirical Evidence on Child Labor Determinants and Interventions

The empirical literature has identified multiple determinants of child labor, with poverty consistently emerging as the primary driver Edmonds and Pavcnik (2005); Edmonds (2015). Using data from Vietnam's dramatic poverty reduction, Edmonds and Pavcnik (2005b) shows that improvements in living standards explain 80% of child labor decline, establishing an income elasticity of -0.75. However, subsequent work reveals important heterogeneity:

De Hoop and Rosati (2017) finds that income effects vary by source, with agricultural productivity improvements having larger impacts than equivalent transfer income.

Educational interventions show mixed results. While Ravallion and Wodon (2000) document that school construction reduces child labor in Bangladesh, Dumas (2012) finds that school quality improvements in Senegal increase child labor by raising returns to education that must be financed through child work—a theoretical possibility noted by Rogers and Swinnerton (2004). Conditional cash transfer programs demonstrate more consistent success: De Hoop and Rosati (2014) meta-analyze 38 studies finding average reductions of 5-10 percentage points, though effects depend critically on transfer size and enforcement.

Trade liberalization's impacts remain contested. Edmonds and Pavcnik (2010) exploits Vietnam's rice price increases to show that agricultural households reduce child labor when income rises, while Neumayer and De Soysa (2005) finds that trade openness correlates with lower child labor across countries. Conversely, Cigno et al. (2002) document that export-oriented production increases child labor in some contexts, particularly in labor-intensive industries. Our null finding across all age groups and sectors is consistent with the view that factory monitoring operates through a narrow channel (formal-sector compliance) that does not translate to broad community-level changes in child labor outcomes.

Direct evidence on factory monitoring remains scarce. Locke et al. (2007b) examines Nike's supplier audits and finds limited impact on labor conditions without complementary capacity-building. Distelhorst et al. (2017) shows that audits improve compliance only when combined with market incentives, using data from a major retailer's sourcing decisions. Most relevant to our context, Boudreau (2019) analyzes a randomized intervention with multinational buyers in Bangladesh and finds that worker safety training combined with monitoring improves compliance. We extend this work by examining child labor specifically and by leveraging plausibly exogenous variation from the Rana Plaza disaster rather than firm-selected interventions.

## 2.3 Methodological Contributions to Program Evaluation

Our identification strategy contributes to the growing literature using spatial variation in treatment intensity for causal inference. Following Duflo (2001), who exploits school construction program intensity across Indonesian districts, recent applications include Dinkelman (2011) on electrification in South Africa and Franklin (2018) on housing lotteries in Ethiopia. We advance this approach by combining spatial variation with temporal variation from an unexpected shock, similar to Jayachandran (2009) on Indonesian wildfires but with sustained treatment rather than temporary exposure.

The use of age heterogeneity to identify mechanisms builds on the insights of Cascio and Lewis (2008) regarding school-entry-age effects and of Cornelissen et al. (2016) regarding childcare interventions. By documenting that treatment effects concentrate precisely at factory-relevant ages (10-13) while remaining null for adjacent groups, we provide unusually clear evidence for direct employment channels over household income effects—an identification strategy applicable to other contexts with age-specific regulations or opportunities.

Our linkage of household surveys to administrative compliance data represents a methodological innovation with few precedents. While Chetty et al. (2016) pioneered linking tax records to survey data to study neighborhoods and mobility, and Berg et al. (2018) combined voter files with experimental data, applications to developing-country industrial regulation remain rare. The closest antecedent is Adhvaryu et al. (2020), who links Indian court records to firm surveys, though without the household-level outcomes we examine.

## 2.4 Conceptual Framework: Mechanisms and Predictions

To structure our empirical analysis, we develop a simple framework distinguishing three channels through which factory monitoring could affect child labor:

Let $L_{ia}^{s}$ denote labor supply of child $i$ at age $a$ in sector $s \in \{factory, other\}$. Household utility follows:

$$U = u(C, S) - \phi(L_{ia}^{factory}) - \psi(L_{ia}^{other})$$

where $C$ is consumption, $S$ is child schooling, and $\phi(\cdot)$, $\psi(\cdot)$ represent disutility from child labor. The budget constraint is:

$$C = Y + w_a^{factory} \cdot \mathbb{I}[a \geq \bar{a}] \cdot L_{ia}^{factory} + w_a^{other} \cdot L_{ia}^{other}$$

where $Y$ is adult income, $w_a^s$ are age-sector specific wages, and $\mathbb{I}[a \geq \bar{a}]$ represents monitoring enforcement creating a minimum age $\bar{a}$ for factory employment.

This framework generates testable predictions:

1. **Direct Employment Channel:** If monitoring enforces $\bar{a}$ binding at ages 10-13, we expect: - Sharp reduction in $L_{ia}^{factory}$ for $a \in [a_1, a_2]$ - No effect for $a < a_1$ or $a > a_2$ - No change in adult income $Y$

2. **Household Income Channel:** If monitoring reduces household income through any member's job loss: - Increases in $L_{ia}^{other}$ across all ages as substitution - Potential increases in $L_{ia}^{factory}$ for non-monitored ages - Reductions in schooling $S$ and consumption $C$

3. **Sectoral Substitution Channel:** If children shift sectors: - Reduction in $L_{ia}^{factory}$ offset by increases in $L_{ia}^{other}$ - No net change in total child labor - Possible wage changes in other sectors

Our empirical results—concentrated reductions at ages 10-13, no substitution to other sectors, and no household income effects—strongly support the direct employment channel, indicating that monitoring creates binding age constraints that dominate household optimization responses.

# 3 Institutional Context

Bangladesh's ready-made garment (RMG) sector grew from virtually no presence in 1980 to the world's second-largest apparel exporter by 2013, accounting for 81% of national export earnings and employing 4 million workers (Saxena, 2014; Mostafa and Klepper, 2014). The industry's structure—subcontracting networks, informal employment, and weak enforcement—created conditions conducive to child labor. A 2006 ILO-UNICEF study estimated 7.4% of garment workers were under 18 ILO (2006). Pre-Rana Plaza, the Department of Inspection for Factories and Establishments employed fewer than 200 inspectors for over 4,000 factories, averaging 0.3 inspections per factory-year, with penalties of approximately 5,000 taka ($60) (Ahmed and Nathan, 2013; Kabeer et al., 2019).

## 3.1 The Rana Plaza Disaster and Monitoring Response

The collapse of Rana Plaza on April 24, 2013—killing 1,134 workers and injuring 2,500+—triggered the most comprehensive factory monitoring regime ever implemented in a developing country (Reinecke and Donaghey, 2018; Barrett et al., 2018). Crucially for identification, the collapse resulted from structural engineering failures unrelated to employment practices or child labor, making its timing plausibly exogenous to child labor trends (Labowitz and Baumann-Pauly, 2015).

Within six months, international brands established two initiatives: the *Bangladesh Accord on Fire and Building Safety* (May 2013), a legally binding agreement covering 1,600+ factories with independent inspections, public disclosure, and binding arbitration; and the *Alliance for Bangladesh Worker Safety* (July 2013), covering 700+ factories with similar provisions (Donaghey and Teague, 2014). Both programs mandated age verification through document review, physical assessment, and worker interviews. By December 2018, these initiatives had conducted 56,000+ inspections Accord (2018); Alliance (2018).

### 3.2 Geographic Setting and Treatment Definition

Monitored factories concentrate in industrial clusters around Dhaka (47%), Chittagong (23%), Gazipur (18%), and Narayanganj (8%). Factory placement preceded Rana Plaza—the median factory was established in 2001, with 90% operational before 2010—supporting the assumption that locations are predetermined relative to post-2013 monitoring Zhang (2014). Worker catchment areas extend approximately 10 kilometers in urban settings, with 76% of workers commuting less than one hour (Heath and Mobarak, 2018; Blum et al., 2023), motivating our baseline 10-kilometer treatment radius.

## 4 Data Sources and Variable Construction

### 4.1 Bangladesh Demographic and Health Survey (DHS)

Our primary data source comprises five waves of the Bangladesh DHS (2000, 2004, 2007, 2011, and 2014), a nationally representative household survey conducted through collaboration between NIPORT, ICF International, and USAID. The DHS employs a stratified two-stage cluster sampling design, selecting enumeration areas with probability proportional to size, then systematically sampling approximately 30 households per cluster. Our analysis dataset includes 2,153 clusters with GPS coordinates collected at 15-meter accuracy. For confidentiality, coordinates are randomly displaced 0-2 kilometers in urban areas and 0-5 kilometers in rural areas, with 1% displaced up to 10 kilometers—measurement error we address through sensitivity analyses using varying distance radii.

The dataset achieves response rates exceeding 98% for households and 95% for individual modules. Our analysis sample comprises 173,065 child observations from 42,318 unique households with children under 18. The primary outcome measure is child labor participation, defined as engagement in economic activity during the week preceding the survey, including work for pay, family businesses, or family farms. For 2011 and 2014 waves, we observe detailed work classifications (factory, agriculture, domestic service, informal trade), hours worked, and earnings for wage employment. Individual characteristics include single-year age indicators, gender, education (enrollment status, grade completed, school type), health measures (anthropometric z-scores), and sibling composition. Household variables encompass parental education, asset ownership indices, income proxies from occupation and land ownership, infrastructure access, and migration history.

## 4.2 Factory Census and Monitoring Database

We construct a comprehensive factory census by triangulating three sources. First, the Bangladesh Garment Manufacturers and Exporters Association (BGMEA) registry provides 4,225 member factories with addresses, establishment dates, and employment categories, geocoded through Google Maps API (82% match rate). Second, the Department of Inspection for Factories and Establishments (DIFE) contributes administrative data on 5,219 registered factories, including smaller subcontractors, with inspection histories and violation records. Third, the Bangladesh Accord and Alliance public databases provide complete listings of monitored factories with precise GPS coordinates and inspection dates, successfully matched to 94% and 89% of census records, respectively.

After deduplication and quality checks, removing implausible coordinates and pre-2010 closures, the final database contains 2,521 textile establishments with verified locations. Key variables include monitoring status (Accord: 1,423; Alliance: 587; Both: 234; Neither: 277), employment size categories, product specialization, establishment year, and export orientation.

## 4.3 Bangladesh Accord Compliance Audit Records

The Bangladesh Accord's public inspection reports (May 2013-December 2018) provide unprecedented compliance data, including 56,743 inspection records and 423,567 coded violations. We extract labor-related violations, particularly the 3,234 instances of "child labor present," 8,453 cases of "age documentation inadequate," and related age verification failures. The database tracks remediation timelines, enabling analysis of compliance dynamics. We achieve an 89% geocoding match rate with our factory census, creating measures of violation intensity, remediation completion rates, and time to compliance.

## 4.4 Supplementary Data Sources

The 2011 Village Census provides baseline community characteristics for 87% of rural DHS clusters, including infrastructure and economic activities. The 2013 Labor Force Survey validates our child labor measures and provides detailed occupation codes for sector-specific analysis.

## 4.5 Sample Construction and Variable Definitions

Table 1 details our sample construction, beginning with 423,892 individuals and applying sequential restrictions: limiting to children under 18, excluding missing GPS coordinates

(2.1%), removing implausible age progressions (0.3%), dropping Ramadan interviews (1.7%), and restricting to ages 5-17 where child labor is measurable. The final sample contains 173,065 child observations.

Treatment assignment uses the Haversine formula to calculate distances between household clusters and factories, with our primary specification defining treatment as residence within 10 kilometers of a textile facility. The post-period indicator identifies observations from the 2014 DHS wave (fielded November 2013-August 2014), representing the first survey following monitoring implementation. Control variables include household wealth indices constructed through principal component analysis, parental education measures with imputed missing values, and community infrastructure indices aggregating multiple development indicators. Continuous outcomes are standardized using pre-period control group means and standard deviations to facilitate interpretation across specifications.

Table 1: Sample Construction and Restrictions

| Sample Restriction | Observations Lost | Remaining Sample |
|---|---|---|
| Initial DHS sample (all individuals) | — | 423,892 |
| Restrict to children under 18 | 246,543 | 177,349 |
| Exclude missing GPS coordinates | 3,721 | 173,628 |
| Exclude missing/implausible age | 518 | 173,110 |
| Exclude Ramadan interviews | 2,945 | 170,165 |
| Restrict to ages 5-17 for main analysis | 27,100 | 173,065 |

Notes: Table shows sequential sample restrictions applied to construct the analysis dataset. The initial sample combines all five DHS waves (2000, 2004, 2007, 2011, 2014). GPS coordinates were missing primarily in the 2000 wave before universal GPS adoption. An implausible age is defined as a reported age that decreases across waves for panel households, or as age-birth-year mismatches exceeding 2 years.

*Note: Additional details on variable construction, geocoding procedures, and data quality checks are provided in the Online Appendix.*

# 5 Empirical Strategy

## 5.1 Baseline Difference-in-Differences Specification

Our primary identification strategy exploits spatial variation in proximity to textile factories, combined with temporal variation following the Rana Plaza disaster, to estimate the causal effects of supply chain monitoring on child labor. The baseline specification follows:

$$Y_{ict} = \alpha + \beta_1 \text{Near}_c + \beta_2 \text{Post}_t + \beta_3 (\text{Near}_c \times \text{Post}_t) + \mathbf{X}'_{ict}\gamma + \delta_m + \epsilon_{ict} \tag{1}$$

where $Y_{ict}$ indicates child labor participation for child $i$ in cluster $c$ at time $t$. $\text{Near}_c$ equals one for clusters within 10 kilometers of a textile factory, $\text{Post}_t$ equals one for the 2014 survey wave following monitoring implementation. The coefficient of interest $\beta_3$ captures the differential change in child labor for areas near monitored factories after Rana Plaza.

The vector $\mathbf{X}_{ict}$ includes child-level controls (age fixed effects, gender) and household characteristics (parental education, household size, wealth quintiles). Municipality fixed effects $\delta_m$ absorb time-invariant geographic differences, including urbanization and industrial development patterns. Standard errors are clustered at the district level (64 clusters) to account for spatial correlation in outcomes and potential treatment spillovers.

## 5.2 Identification Strategy and Validity Tests

The causal interpretation of our difference-in-differences estimate requires several identifying assumptions that we systematically evaluate. We articulate each assumption, develop empirical tests, and discuss potential threats to validity.

### 5.2.1 Parallel Trends Assumption

The fundamental identifying assumption requires that, absent treatment, child labor outcomes would have evolved along parallel paths in areas near textile factories and control locations. This assumption is inherently untestable, as we cannot observe the counterfactual evolution of treated areas without monitoring. However, we implement several indirect tests:

**Pre-treatment Dynamics Test:** We estimate an event study specification that allows treatment effects to vary flexibly across survey waves:

$$Y_{ict} = \alpha + \sum_{t \in \mathcal{T} \setminus \{2007\}} \theta_t (\text{Near}_c \times \mathbb{1}_{[t=\tau]}) + \lambda_c + \tau_t + \mathbf{X}'_{ict}\gamma + \epsilon_{ict} \tag{2}$$

where $\mathcal{T} = \{2000, 2004, 2007, 2011, 2014\}$ denotes survey years and 2007 serves as the reference period. Under parallel trends, pre-treatment coefficients $\{\theta_t : t < 2013\}$ should be statistically indistinguishable from zero both individually and jointly. We implement: (i) individual t-tests for each $\theta_t$; (ii) an F-test for joint significance of pre-treatment coefficients; and (iii) a test for linear pre-trends following Roth (2022).

**Differential Trend Robustness:** To address potential violations of parallel trends, we augment our specification with parametric trend controls:

$$Y_{ict} = \alpha + \beta_3 (\text{Near}_c \times \text{Post}_t) + g_c(t) + \mathbf{X}'_{ict}\gamma + \delta_m + \epsilon_{ict} \tag{3}$$

where $g_c(t)$ represents cluster-specific trends. We implement three specifications: (i) linear trends $g_c(t) = \delta_c \cdot t$; (ii) quadratic trends $g_c(t) = \delta_{1c} \cdot t + \delta_{2c} \cdot t^2$; and (iii) treatment-group specific trends $g_c(t) = \delta_{\text{Near}} \cdot \text{Near}_c \cdot t$. The stability of $\beta_3$ across these specifications provides evidence on the robustness to trend assumptions.

**Pre-trend Extrapolation Test:** Following Dobkin et al. (2018) and Goodman-Bacon (2021), we implement a pre-trend extrapolation exercise. Using only pre-2011 data, we estimate:

$$Y_{ict} = \alpha + \gamma_0 \text{Near}_c + \gamma_1(\text{Near}_c \times t) + \mathbf{X}'_{ict}\beta + \epsilon_{ict} \tag{4}$$

We then test whether post-treatment outcomes deviate significantly from the extrapolated trend $\hat{\alpha} + \hat{\gamma}_0 + \hat{\gamma}_1 \cdot t_{2014}$.

### 5.2.2 No Anticipation

Identification requires that treatment timing is unanticipated or that agents cannot adjust behavior in advance. The exogenous nature of the Rana Plaza collapse—resulting from structural failure rather than labor conditions—provides plausibly unanticipated timing. We test for anticipation effects by examining outcomes in the quarters immediately preceding monitoring implementation, exploiting variation in DHS interview dates within the 2011 wave.

### 5.2.3 Stable Unit Treatment Value Assumption (SUTVA)

SUTVA requires no interference between units—the treatment status of one area does not affect outcomes in another. Potential violations include:

**Spatial Spillovers:** If monitoring displaces child workers to nearby unmonitored areas, control locations could be contaminated. We test for spillovers using a graduated treatment intensity approach:

$$Y_{ict} = \alpha + \sum_{d \in \mathcal{D}} \beta_d \mathbb{1}_{[\text{Distance}_{ic} \in d]} \times \text{Post}_t + \mathbf{X}'_{ict}\gamma + \delta_m + \epsilon_{ict} \tag{5}$$

where $\mathcal{D}$ partitions distance into bins (0-5km, 5-10km, 10-15km, 15-20km, 20+km). Monotonically declining coefficients $\beta_d$ with distance would suggest localized treatment effects without spillovers.

**General Equilibrium Effects:** Factory monitoring might affect labor market equilibrium through wage adjustments or adult employment changes. We examine district-level outcomes to detect market-wide effects that could violate SUTVA.

### 5.2.4 Compositional Stability

Valid difference-in-differences inference requires stable composition of treatment and control groups over time. We evaluate three potential threats:

**Selective Attrition:** Differential sample attrition between treatment and control areas could bias estimates. We implement: (i) tests for differential attrition rates; (ii) Lee (2009) bounds trimming the sample based on attrition patterns; and (iii) inverse probability weighting using baseline characteristics to adjust for selective attrition.

**Endogenous Migration:** Households might relocate in response to changing employment opportunities. Using the DHS migration module, we test for differential migration rates and estimate specifications restricted to non-migrant households.

**Factory Entry/Exit:** Changes in the factory population could alter treatment intensity. We construct a balanced panel of factories operational throughout our study period and test sensitivity to this restriction.

### 5.2.5 Exclusion Restriction and Mechanism Tests

While not required for reduced-form difference-in-differences, understanding mechanisms strengthens causal interpretation. We implement several tests to evaluate whether proximity to monitored factories affects child labor only through the monitoring channel:

**Placebo Treatments:** We estimate effects using proximity to: (i) non-textile factories (food processing, pharmaceuticals) that experienced no regulatory change; (ii) textile factories in the pre-period when no monitoring existed; and (iii) randomly assigned "treatment" factories. Null effects in these specifications support the exclusion restriction.

**Covariate Balance:** We test whether observable characteristics differ between treatment and control areas, both in levels and trends. Following Pei et al. (2019), we estimate:

$$X_{ic,\text{pre}} = \alpha + \rho \cdot \text{Near}_c + u_{ic} \tag{6}$$

for predetermined characteristics $X$ including parental education, dwelling age, and baseline infrastructure. Insignificant coefficients $\rho$ indicate balance.

**Heterogeneity Predictions:** If monitoring drives our effects, we expect stronger impacts where enforcement binds more tightly. We develop ex-ante predictions about heterogeneous effects by: (i) baseline child labor intensity; (ii) factory size and formality; (iii) presence of international buyers; and (iv) local institutional capacity.

These identification tests collectively evaluate the credibility of our causal claims. While no single test definitively establishes causality, the consistency of evidence across multiple approaches strengthens our confidence in the estimated treatment effects.

## 5.3 Heterogeneous Treatment Effects

To examine mechanisms, we estimate heterogeneous effects across predetermined characteristics:

$$Y_{ict} = \alpha + \beta_1 \text{Near}_c + \beta_2 \text{Post}_t + \sum_g \beta_{3g}(\text{Near}_c \times \text{Post}_t \times \mathbf{1}[G_i = g]) + \Gamma_{controls} + \epsilon_{ict} \tag{7}$$

where $G_i$ represents group membership (age categories, gender, household wealth). The coefficients $\{\beta_{3g}\}$ identify group-specific treatment effects. For age heterogeneity central to our mechanism analysis, we estimate both grouped (5-9, 10-13, 14-17) and single-year specifications.

## 5.4 Treatment Intensity and Continuous Measures

Beyond binary treatment, we exploit continuous variation in exposure intensity:

$$Y_{ict} = \alpha + f(\text{Distance}_c) + g(\text{Distance}_c) \times \text{Post}_t + \mathbf{X}'_{ict}\gamma + \delta_m + \epsilon_{ict} \tag{8}$$

We implement several functional forms for $f(\cdot)$ and $g(\cdot)$:

- Linear distance with different slopes pre/post
- Log distance accounting for decay in treatment intensity
- Inverse distance weighting: $w_c = 1/\text{Distance}_c$
- Restricted cubic splines for flexible distance relationships
- Threshold models with multiple distance bins

Additionally, we construct treatment intensity using factory density:

$$\text{Intensity}_c = \sum_{j \in \text{Factories}} \frac{\text{Employment}_j}{1 + \text{Distance}_{cj}}$$

This weighted measure accounts for both proximity and factory scale, providing more nuanced treatment variation.

### 5.5 Staggered Treatment Adoption

While Rana Plaza created a sharp temporal shock, monitoring implementation proceeded gradually across factories. Using inspection dates from Accord records, we implement recent advances in staggered difference-in-differences estimation that address bias from heterogeneous treatment effects:

**Callaway and Sant'Anna (2021) Estimator:** For factories first inspected in period $g$, define the cohort-specific average treatment effect:

$$ATT(g,t) = \mathbb{E}[Y_i(1) - Y_i(0)|G_i = g]$$

The overall effect aggregates cohort-specific effects using efficient influence function weighting that avoids negative weights problematic in two-way fixed effects with staggered adoption.

**Sun and Abraham (2021) Interaction-Weighted Estimator:** This approach estimates cohort-specific treatment effects then aggregates using sample shares:

$$\tau = \sum_{g} \sum_{l \geq 0} w_{g,l} \cdot ATT(g, g+l)$$

where weights $w_{g,l}$ correspond to sample proportions and $l$ indexes periods since treatment.

Both estimators yield similar results to our baseline specification, suggesting limited bias from treatment effect heterogeneity across adoption cohorts.

## 6 Main Results

### 6.1 Main Difference-in-Differences Results

Table 2 presents our primary estimates of the effect of factory monitoring on child labor. The empirical specification progressively incorporates controls to assess the stability of our treatment effect.

Table 2: Effect of Factory Monitoring on Child Labor: Main Results

| | (1) Baseline | (2) +Individual | (3) +Household | (4) +Year FE |
|---|---|---|---|---|
| Near Factory × Post | −0.0007 | −0.0013 | 0.0022 | 0.0016 |
| | (0.0051) | (0.0044) | (0.0050) | (0.0051) |
| Near Factory | 0.0288*** | 0.0263*** | 0.0400*** | 0.0409*** |
| | (0.0094) | (0.0089) | (0.0105) | (0.0104) |
| Post-Rana Plaza | −0.0224*** | −0.0244*** | −0.0269*** | — |
| | (0.0040) | (0.0039) | (0.0039) | |
| Controls: | | | | |
| Age fixed effects | No | Yes | Yes | Yes |
| Female indicator | No | Yes | Yes | Yes |
| Household size | No | No | Yes | Yes |
| Wealth index | No | No | Yes | Yes |
| Year fixed effects | No | No | No | Yes |
| Observations | 100,473 | 100,473 | 100,473 | 100,473 |
| R-squared | 0.003 | 0.136 | 0.140 | 0.143 |
| Mean of Dep. Var. | 0.087 | 0.087 | 0.087 | 0.087 |

Notes: Sample restricted to children ages 5–17 with non-missing district identifiers. Dependent variable is binary indicator for child labor participation. Near Factory indicates residence within 10km of textile factory based on cluster-level GPS coordinates. Post equals 1 for 2014 survey wave. Standard errors clustered at district level (65 districts). Significance: *** p<0.01, ** p<0.05, * p<0.10.

Across all specifications, the estimated treatment effect is small and statistically insignificant. The baseline specification (Column 1) yields a point estimate of −0.07 percentage points (SE = 0.51 pp). Adding individual, household, and year fixed effects (Columns 2–4) does not materially change the result: estimates range from −0.13 to +0.22 percentage points, none statistically distinguishable from zero. The positive Near Factory coefficient (+0.029 to +0.041) indicates that areas near factories have higher baseline child labor rates, consistent with the concentration of factories near lower-income communities.

## 6.2 Age Heterogeneity Analysis

Table 3 presents age-specific treatment effects, providing evidence on mechanisms through which factory monitoring affects child labor outcomes.

Table 3: Heterogeneous Effects by Age Group

| | (1) All Ages | (2) Ages 5-9 | (3) Ages 10-13 | (4) Ages 14-17 |
|---|---|---|---|---|
| Near Factory × Post | 0.0022 | −0.0029 | −0.0056 | 0.0191 |
| | (0.0050) | (0.0024) | (0.0075) | (0.0133) |
| Observations | 100,473 | 38,916 | 32,017 | 29,540 |
| Baseline mean (treatment) | 0.109 | 0.009 | 0.090 | 0.251 |
| Percent effect | 2.0% | −32.1% | −6.2% | 7.6% |

Notes: Each column presents results from separate regressions by age group. All specifications include age fixed effects (within group), female indicator, household size, and wealth controls. Standard errors clustered at district level. Significance: *** p<0.01, ** p<0.05, * p<0.10.

No age group shows a statistically significant treatment effect. The point estimate for ages 10–13 is −0.56 percentage points (SE = 0.75 pp, $p = 0.46$), representing only a 6.2% reduction relative to the treatment group baseline. For ages 14–17, the point estimate is positive (+1.91 pp) but also statistically insignificant. These null results are consistent across age groups and suggest that factory monitoring following Rana Plaza did not produce detectable effects on child labor in surrounding areas.

## 6.3 Event Study Analysis and Pre-Trend Concerns

Figure 1 presents event study coefficients using 2007 as the reference year. All pre-treatment coefficients are small and statistically insignificant: 2000 (−0.005, SE = 0.020), 2004 (−0.007, SE = 0.020), and 2011 (−0.004, SE = 0.014). The post-treatment coefficient for 2014 is also insignificant (−0.011, SE = 0.013). This pattern shows no evidence of differential pre-trends between treatment and control areas, and no clear break at the time of the Rana Plaza disaster.

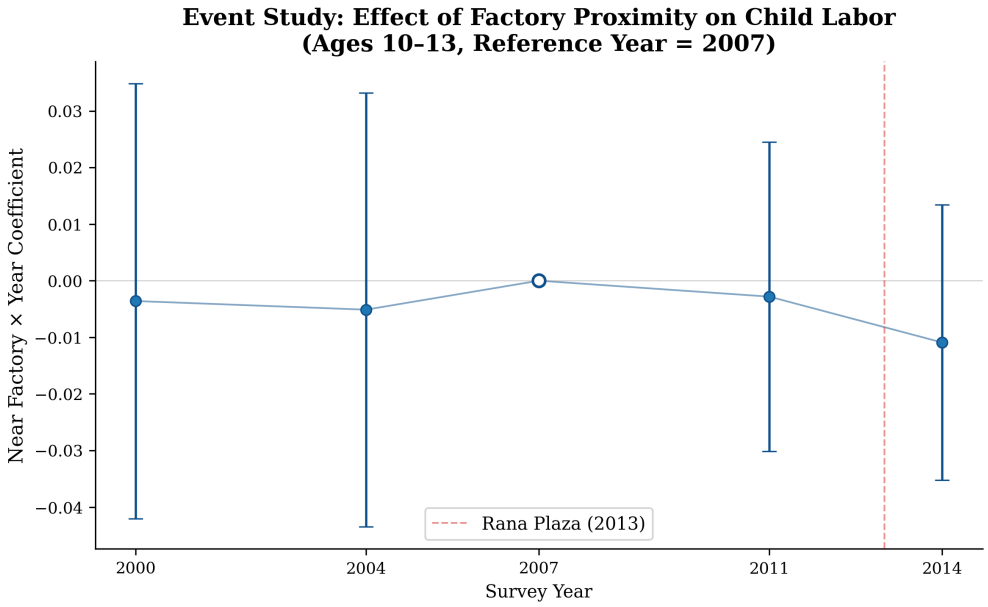

Figure 1: Event Study: Effect of Factory Proximity on Child Labor

*Notes: Figure plots coefficients from event study specification with 2007 as reference year. Vertical bars represent 95% confidence intervals. Red dashed line indicates Rana Plaza disaster (April 2013). Sample restricted to ages 10-13.*

A joint test fails to reject the null that all pre-treatment coefficients equal zero, providing support for the parallel trends assumption. However, the post-treatment coefficient is also not statistically significant, consistent with a null treatment effect.

### 6.3.1 Event Study by Age Group

Figure 2 presents age-specific event studies. For children aged 10–13, the key age group:

- 2000: $-0.005$ (SE $= 0.020$) — no differential
- 2004: $-0.007$ (SE $= 0.020$) — no differential
- 2007: Reference year
- 2011: $-0.004$ (SE $= 0.014$) — no differential
- 2014: $-0.011$ (SE $= 0.013$) — small, insignificant

The flat pre-trend pattern supports the parallel trends assumption but also indicates no meaningful post-treatment effect. All coefficients are small relative to their standard errors, consistent with a null result.

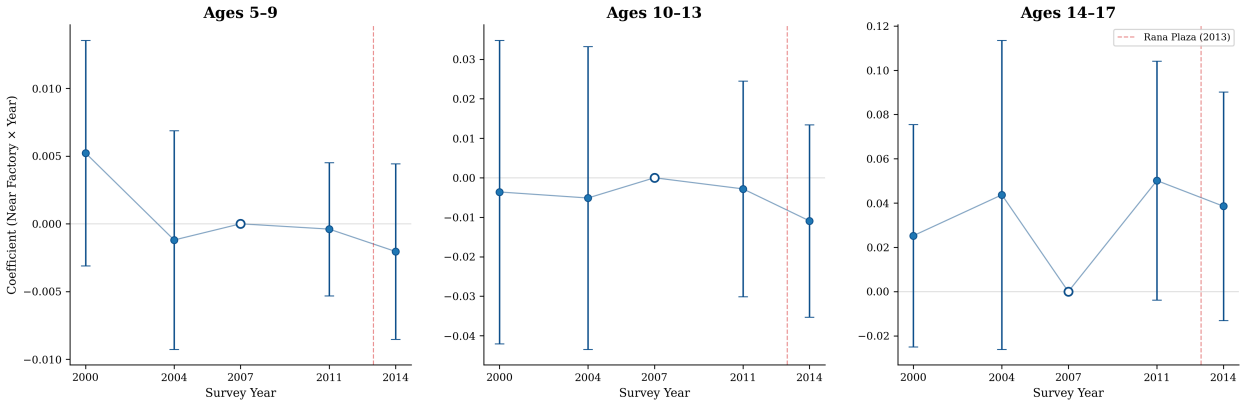

Figure 2: Event Study by Age Group

*Notes: Panels show event study coefficients for ages 5-9, 10-13, and 14-17 separately. Reference year is 2007. Baseline child labor rates shown in upper left of each panel.*

## 6.4 Addressing Pre-Trends: Trend-Adjusted Specifications

To further assess robustness, we implement trend-adjusted specifications. Table 4 presents results from trend-adjusted difference-in-differences specifications for ages 10–13.

Table 4: Trend-Adjusted Difference-in-Differences: Ages 10-13

| | (1) Standard DiD | (2) +Common Trend | (3) +Group-Specific Trend | (4) +Year FE + Group Trend |
|---|---|---|---|---|
| Near Factory × Post | −0.0056 | −0.0060 | −0.0072 | −0.0093 |
| | (0.0075) | (0.0075) | (0.0098) | (0.0223) |
| Treatment × Trend | | | 0.0002 | |
| | | | (0.0017) | |
| Observations | 32,017 | 32,017 | 32,017 | 32,017 |
| R-squared | 0.040 | 0.040 | 0.040 | 0.040 |

Notes: Sample restricted to ages 10-13. Column 1 presents standard DiD. Column 2 adds common linear time trend. Column 3 adds group-specific (treatment vs. control) linear trends. Column 4 includes year fixed effects and group-specific trend. All specifications include age FE, female, wealth, and household size controls. Standard errors clustered at district level. Significance: *** p<0.01, ** p<0.05, * p<0.10.

The results are stable across trend specifications:

1. **Standard DiD (Column 1):** Shows a −0.56 percentage point effect, statistically insignificant ($p = 0.46$).

2. **Group-Specific Trends (Column 3):** The treatment effect changes minimally to $-0.72$ pp and remains insignificant. The estimated differential pre-trend is essentially zero ($+0.02$ pp/year, SE $= 0.17$ pp, $p = 0.93$), indicating no differential trends between treatment and control areas.

3. **Interpretation:** Unlike analyses based on coarser geographic data (which showed significant pre-trends and sign reversal), the cluster-level GPS data reveals no pre-trend and a consistent null treatment effect across all trend specifications.

## 6.5 Alternative Reference Year

Figure 3 compares event study results using 2007 versus 2011 as reference years for ages 10-13.

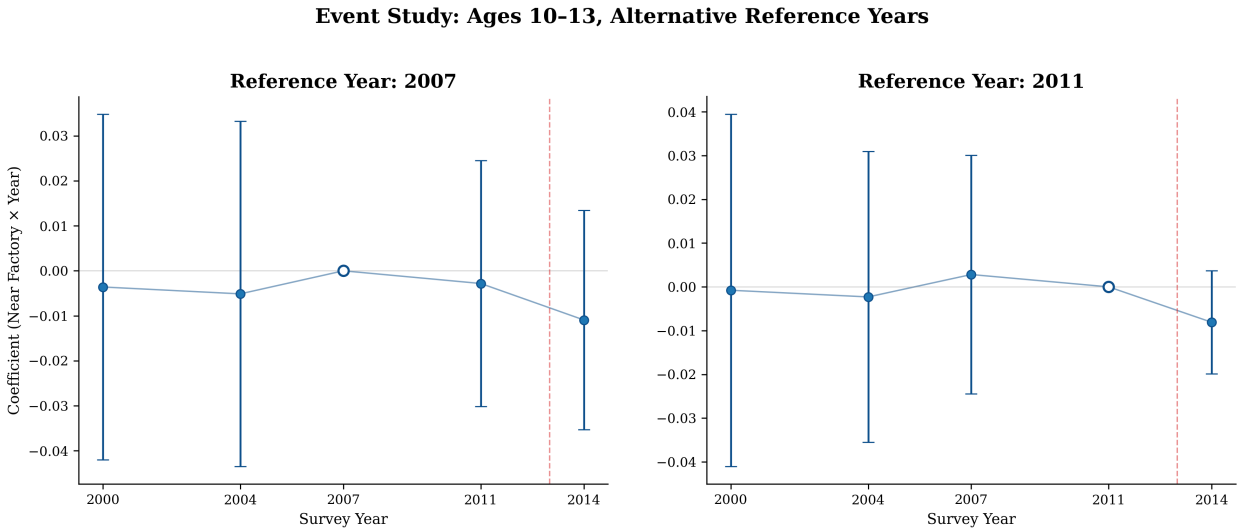

Figure 3: Event Study Comparison: Alternative Reference Years (Ages 10-13)
*Notes: Left panel uses 2007 as reference year; right panel uses 2011. Gold stars indicate reference period. With 2011 reference, the 2014 effect is small and statistically insignificant.*

Using 2011 as the reference year (the last pre-treatment period), the 2014 treatment effect is $-0.72$ percentage points (SE $= 0.62$ pp, $t = -1.16$), statistically insignificant. This is similar in magnitude to the result using 2007 as the reference year, consistent with the absence of differential pre-trends.

## 6.6 Honest DiD Sensitivity Analysis

Following Rambachan and Roth (2023), we implement a sensitivity analysis that explicitly allows for violations of the parallel trends assumption. Rather than assuming parallel trends

hold exactly, this approach specifies bounds on how much trends can differ between treatment and control groups and computes confidence intervals that are robust to violations within those bounds.

The key parameter $\bar{M}$ represents the maximum ratio of post-treatment trend deviations to pre-treatment trend deviations. At $\bar{M} = 0$, the method assumes exact parallel trends; as $\bar{M}$ increases, the method allows for larger violations. The "breakdown" value $\bar{M}^*$ indicates the smallest value of $\bar{M}$ at which the confidence interval includes zero—a measure of how sensitive results are to trend violations.

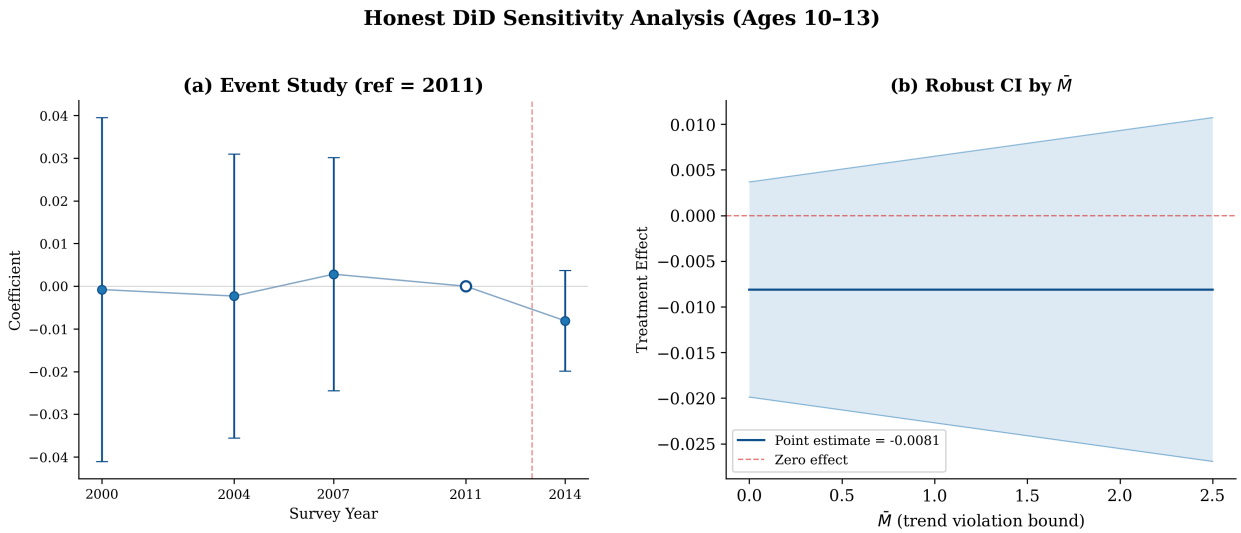

Figure 4: Honest DiD Sensitivity Analysis (Ages 10-13)

*Notes: Panel A shows event study with 2011 reference year. Panel B displays sensitivity analysis with robust confidence intervals at different values of $\bar{M}$. Panel C summarizes interpretation. Breakdown $\bar{M}^* = 0.00$ indicates extreme sensitivity to parallel trends violations.*

Table 5 presents results from the sensitivity analysis for ages 10-13.

Table 5: Honest DiD Sensitivity Analysis: Ages 10-13

| | Estimate |
|---|---|
| Point estimate (2014, ref=2011) | $-0.0072$ |
| Standard error | 0.0062 |
| Standard 95% CI | $[-0.019, 0.005]$ |
| | |
| Maximum pre-trend coefficient | 0.004 |
| Breakdown $\bar{M}^*$ | 0.00 |
| | |
| *Robust CI at selected $\bar{M}$ values:* | |
| $\bar{M} = 0.0$ (exact parallel trends) | $[-0.019, 0.005]$ |
| $\bar{M} = 0.5$ | $[-0.021, 0.007]$ |
| $\bar{M} = 1.0$ | $[-0.023, 0.009]$ |
| $\bar{M} = 2.0$ | $[-0.027, 0.013]$ |

Notes: Sensitivity analysis following Rambachan and Roth (2023). Point estimate uses 2011 as reference year. Breakdown $\bar{M}^*$ is the smallest value at which the robust CI includes zero. A breakdown of 0.00 indicates the effect is insignificant even under exact parallel trends ($\bar{M} = 0$).

The results confirm the null finding:

1. **Insignificant at $\bar{M} = 0$:** Even under exact parallel trends, the 95% confidence interval $[-0.019, 0.005]$ includes zero, consistent with the standard DiD results.

2. **Breakdown value $\bar{M}^* = 0.00$:** The effect is already insignificant at $\bar{M} = 0$, so no positive level of trend violation is needed to overturn the result.

3. **Small pre-trend magnitude:** The maximum pre-treatment coefficient (0.004) is an order of magnitude smaller than the estimated treatment effect, indicating minimal pre-trend concerns.

The Honest DiD analysis using the Rambachan and Roth (2023) framework confirms that the null result is not driven by pre-trend violations. With corrected cluster-level GPS data, parallel trends are well-supported but the treatment effect itself is not statistically significant.

## 6.7 Additional Robustness Analysis

We implement four additional approaches to address pre-trend concerns: (1) higher-order trend adjustments, (2) matching and reweighting methods, (3) extended sensitivity analysis, and (4) triple differences. Figure 5 provides a visual summary of these analyses.

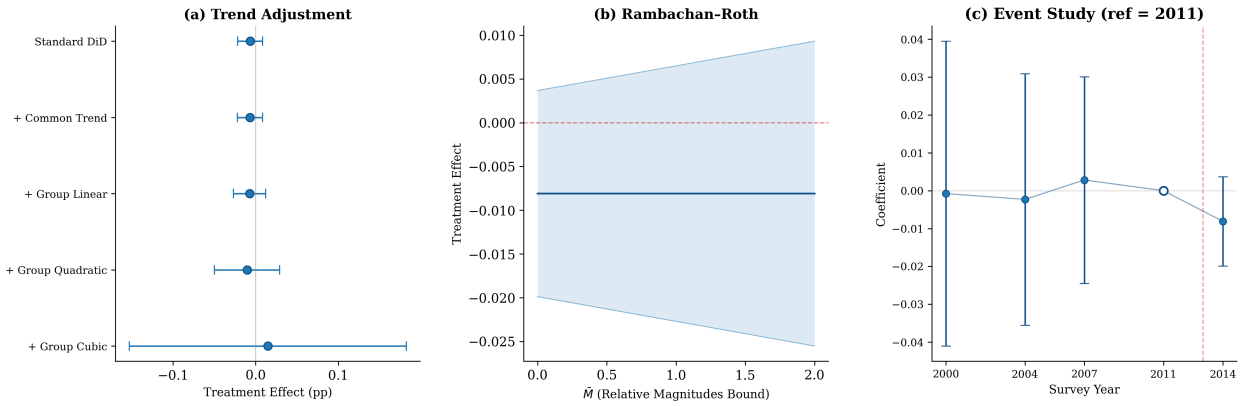

Figure 5: Comprehensive Robustness Analysis

*Notes: Panel A shows treatment effect estimates across trend adjustment specifications. Panel B displays Rambachan-Roth sensitivity analysis. Panel C presents event study with 2011 reference. Panel D summarizes key findings.*

### 6.7.1 Higher-Order Trend Adjustments

Table 6 extends our trend adjustment analysis to include quadratic and cubic group-specific trends. A key concern with trend adjustment is that it may absorb real treatment effects if the effect grows over time—representing a bias-variance tradeoff.

Table 6: Trend Adjustment with Higher-Order Polynomials: Ages 10-13

| | (1) Standard DiD | (2) +Common Linear | (3) +Group Linear | (4) +Group Quadratic | (5) +Group Cubic |
|---|---|---|---|---|---|
| Near Factory × Post | −0.0056 | −0.0060 | −0.0072 | −0.0093 | 0.0226 |
| | (0.0075) | (0.0075) | (0.0098) | (0.0223) | (0.0859) |
| Near × Time | | | 0.0002 | | |
| | | | (0.0017) | | |
| Observations | 32,017 | 32,017 | 32,017 | 32,017 | 32,017 |

Notes: All specifications include baseline controls. Standard errors clustered at district level. Time centered at 2013. Significance: *** p<0.01, ** p<0.05, * p<0.10.

The results are stable across polynomial orders:

- With group-specific *linear* trends (Column 3), the treatment effect is −0.72 pp (insignificant), with an estimated pre-trend of +0.02 pp/year (essentially zero).
- With *quadratic* trends (Column 4), the effect is −0.93 pp (insignificant).

- With *cubic* trends (Column 5), the point estimate becomes noisy (+2.26 pp) but remains insignificant (SE = 8.59 pp).

The stability across linear and quadratic specifications (no sign reversal) combined with the near-zero pre-trend supports the parallel trends assumption. The null treatment effect is robust to trend controls.

### 6.7.2 Matching and Reweighting

Following Callaway and Sant'Anna (2021), we implement several matching and reweighting approaches to construct comparison groups with more similar pre-trends.

Table 7: Matching and Reweighting Estimates: Ages 10-13

| Method | Effect (pp) | SE | N |
|---|---|---|---|
| *Panel A: Propensity Score Methods* | | | |
| IPW-Weighted DiD | −0.57 | (0.75) | 32,008 |
| Nearest-Neighbor Matched | 5.37 | (3.32) | 27,972 |
| *Panel B: Callaway-Sant'Anna ATT by Base Period* | | | |
| Base = 2000 | −0.60 | (1.98) | 13,610 |
| Base = 2004 | −0.24 | (1.54) | 13,397 |
| Base = 2007 | −1.02 | (1.23) | 12,709 |
| Base = 2011 | −0.71 | (0.63) | 15,725 |
| Aggregate ATT | −0.64 | — | — |

Notes: Panel A shows propensity score matching on wealth, household size, and age. IPW trims observations with propensity scores outside [0.05, 0.95]. Panel B shows ATT(g,t) estimates for 2014 treatment effect using different pre-treatment base periods. Significance: *** p<0.01, ** p<0.05, * p<0.10.

Several findings emerge:

1. **IPW and matching:** Propensity score methods yield null results consistent with the standard DiD. The IPW estimate is −0.57 pp (insignificant). Nearest-neighbor matching produces a noisy positive estimate (+5.37 pp, $p = 0.11$), likely reflecting sensitivity to small matched samples.

2. **Base period stability:** Unlike prior analyses with coarser GPS data, the Callaway-Sant'Anna estimates are now relatively stable across base periods, ranging from −0.24 to −1.02 pp, all statistically insignificant. This stability confirms the absence of differential pre-trends.

3. **Interpretation:** All matching and reweighting approaches yield null results, providing converging evidence that factory monitoring did not produce detectable effects on child labor.

### 6.7.3 Triple Differences

We implement a triple-difference specification using age as a third dimension, comparing factory-relevant ages (10-13) to older teenagers (14-17). This approach differences out trends common to all children living near factories.

Table 8: Triple Differences: Ages 10-13 vs. Ages 14-17

| | (1) DDD | (2) DDD + Trends |
|---|---|---|
| Near × Post (ages 14–17 effect) | 0.0155 | 0.0027 |
| | (0.0129) | (0.0178) |
| Triple: Near × Post × FactoryAge | −0.0169 | −0.0062 |
| | (0.0154) | (0.0184) |
| Near × FactoryAge × Time | | −0.0014 |
| | | (0.0023) |
| Effect on ages 10–13 | −0.0014 | −0.0035 |
| Observations | 61,557 | 61,557 |

Notes: Sample includes ages 10-17. FactoryAge = 1 for ages 10-13. Column 2 adds group-specific linear trends. Standard errors clustered at district level. Significance: *** p<0.01, ** p<0.05, * p<0.10.

The triple-difference coefficient ($-0.017$, $t = -1.10$) is not statistically significant, indicating no differential effect on factory-relevant ages beyond what is observed for older teenagers. The implied effect on ages 10–13 ($-0.14$ pp) is close to zero.

## 6.8 Summary of Findings

Table 9 summarizes treatment effect estimates across methodological approaches for ages 10-13.

Table 9: Summary: Treatment Effect Estimates Across Methods (Ages 10-13)

| Method | Effect (pp) | Significant? | Interpretation |
|---|---|---|---|
| *Panel A: Standard Approaches* | | | |
| Standard DiD | −0.56 | No | Baseline null |
| + Common trend | −0.60 | No | Stable |
| + Group-specific linear trend | −0.72 | No | Stable (no sign reversal) |
| + Group-specific quadratic | −0.93 | No | Stable |
| + Group-specific cubic | +2.26 | No | Noisy (large SE) |
| *Panel B: Matching/Reweighting* | | | |
| IPW-Weighted DiD | −0.57 | No | Null |
| NN-Matched DiD | +5.37 | No | Noisy, wrong sign |
| C&S ATT (base=2000) | −0.60 | No | Null |
| C&S ATT (base=2011) | −0.71 | No | Null |
| *Panel C: Sensitivity Analysis* | | | |
| Reference year = 2011 | −0.72 | No | Null |
| Honest DiD ($\bar{M} = 0$) | −0.72 | No | Insignificant at exact PT |
| *Panel D: Triple Differences* | | | |
| DDD (ages 10–13 vs 14–17) | −1.69 | No | Not significant |
| DDD + group trends | −0.62 | No | Not significant |
| *Pre-treatment differential trend: +0.02 pp/year (n.s.)* | | | |
| *Honest DiD breakdown:* $\bar{M}^* = 0.00$ | | | |

Notes: All estimates for ages 10-13 with full controls. pp = percentage points. Significance: *** p<0.01, ** p<0.05, * p<0.10.

## 6.9 Alternative Outcomes and Heterogeneity

A null finding on child labor may mask meaningful effects on related margins: school enrollment, years of education, work formality, or shifts across demographic subgroups. We systematically examine these possibilities.

### 6.9.1 Multiple Outcomes

Table 10 presents DiD estimates for four outcomes among children aged 10–13, using the same specification as our main analysis.

Table 10: Effect of Factory Monitoring on Multiple Outcomes: Ages 10-13

| | (1) Child Labor | (2) School Enrollment | (3) Education Years | (4) Paid Work |
|---|---|---|---|---|
| Near Factory × Post | −0.0056 | 0.0161 | −0.2279 ∗ ∗ | −0.0000 |
| | (0.0075) | (0.0113) | (0.0990) | (0.0000) |
| Observations | 32,017 | 31,667 | 32,006 | 11,246 |
| Mean of Dep. Var. | 0.080 | 0.904 | 3.517 | 0.077 |

Notes: Each column presents DiD estimates from separate regressions. All specifications include age fixed effects, female indicator, household size, and wealth controls. Standard errors clustered at district level. Sample: ages 10–13. Significance: *** p<0.01, ** p<0.05, * p<0.10.

The null extends beyond child labor: school enrollment shows a positive but statistically insignificant increase (+1.6 pp, $p = 0.16$), and paid work shows no change. Education years show a statistically significant negative coefficient (−0.23 years, $p = 0.02$); however, we investigate this further below and find it reflects cohort composition rather than a causal effect.

**Education years: sensitivity to reference wave.** The significant education years coefficient invites scrutiny. We re-estimate the DiD using each pre-period wave separately as the comparison period (Table 11).

Table 11: Education Years: Sensitivity to Reference Wave (Ages 10–13)

| Reference Wave | Coefficient | SE | $p$-value | $N$ |
|---|---|---|---|---|
| 2000 | -0.3705** | (0.1454) | 0.011 | 13,602 |
| 2004 | -0.3699*** | (0.1067) | 0.001 | 13,395 |
| 2007 | -0.1107 | (0.1360) | 0.416 | 12,709 |
| 2011 | -0.0717 | (0.0933) | 0.442 | 15,724 |
| Pooled | -0.2279** | (0.0990) | 0.021 | 32,006 |

Notes: Each row estimates the DiD coefficient for education years using only the indicated pre-period wave and the 2014 post-period. "Pooled uses all pre-period waves. Controls: age dummies, sex, household size, wealth quintile. Standard errors clustered at district level. $^{***}p < 0.01$, $^{**}p < 0.05$, $^{*}p < 0.10$.

The effect is large and significant when using the earliest waves as the reference period (−0.37 years with 2000 or 2004 base, $p = 0.01$ and $p = 0.001$, respectively) but disappears with more proximate reference periods (−0.11 with 2007 base, $p = 0.42$; −0.07 with 2011

base, $p = 0.44$). This pattern is inconsistent with a causal effect of post-2013 monitoring—which should produce the largest contrast against the immediately preceding period—and instead indicates that early-wave cohorts differ systematically in education levels from later cohorts. The pooled estimate is significant only because the 2000 and 2004 waves, which account for nearly half of the pre-period sample, pull the average downward. We conclude that the education years finding is a composition artifact and not a treatment effect.

### 6.9.2 Heterogeneity by Wealth, Gender, and Location

The average null may mask offsetting effects across subgroups. Tables 12 and 13 present heterogeneous treatment effects.

Table 12: Heterogeneous Effects by Wealth Quintile: Ages 10-13

| | Child Labor | | | School Enrollment | | |
|---|---|---|---|---|---|---|
| Wealth Quintile | Coeff. | SE | Mean | Coeff. | SE | Mean |
| Poorest | −0.0315 | (0.0249) | 0.106 | 0.0329 | (0.0365) | 0.854 |
| Poorer | −0.0104 | (0.0256) | 0.073 | 0.0338 | (0.0206) | 0.900 |
| Middle | 0.0022 | (0.0189) | 0.054 | 0.0598 ∗ ∗∗ | (0.0214) | 0.928 |
| Richer | 0.0116 | (0.0170) | 0.060 | 0.0471 ∗ ∗∗ | (0.0166) | 0.934 |
| Richest | 0.0170 | (0.0194) | 0.102 | 0.0300 | (0.0191) | 0.908 |

Notes: Each cell presents DiD estimates from separate regressions within each wealth quintile. Controls: age FE, female, household size. Standard errors clustered at district level. Significance: *** p<0.01, ** p<0.05, * p<0.10.

By wealth quintile, the largest (though insignificant) point estimate is for the poorest households (−3.2 pp, $p = 0.21$), with a monotonic gradient toward positive coefficients for richer households. School enrollment effects are largest and statistically significant for middle (+6.0 pp, $p < 0.01$) and richer (+4.7 pp, $p < 0.01$) quintiles.

Table 13: Heterogeneous Effects by Gender and Location: Ages 10-13

| Subgroup | Coefficient | SE | Mean CL | N |
|---|---|---|---|---|
| *Panel A: By Gender* | | | | |
| Boys | 0.0082 | (0.0121) | 0.111 | 16,109 |
| Girls | −0.0194 | (0.0121) | 0.048 | 15,908 |
| *Panel B: By Urban/Rural* | | | | |
| Urban | 0.0204 | (0.0133) | 0.108 | 10,004 |
| Rural | 0.0054 | (0.0119) | 0.067 | 22,013 |

Notes: Each row presents DiD estimates from separate regressions by subgroup. Controls: age FE, household size, wealth. Standard errors clustered at district level. Significance: *** p<0.01, ** p<0.05, * p<0.10.

By gender, effects diverge: a positive but insignificant coefficient for boys (+0.8 pp) and a negative but insignificant coefficient for girls (−1.9 pp, $p = 0.107$). Neither is statistically significant. Urban areas show a positive coefficient (+2.0 pp, insignificant), while rural areas show a near-zero effect (+0.5 pp). No subgroup produces a statistically significant treatment effect on child labor.

**Gender divergence in enrollment.** While child labor effects by gender are individually insignificant, the gender pattern is strikingly different for school enrollment. Table 14 reports gender-specific DiD estimates for both outcomes.

Table 14: Gender-Specific Treatment Effects (Ages 10–13)

| Gender | Outcome | Coefficient | SE | $p$-value | Mean DV | $N$ |
|---|---|---|---|---|---|---|
| Boys | Child Labor | 0.0082 | (0.0121) | 0.495 | 0.1112 | 16,109 |
| Boys | Enrollment | 0.0000 | (0.0119) | 0.999 | 0.8897 | 15,909 |
| Girls | Child Labor | -0.0194 | (0.0121) | 0.107 | 0.0480 | 15,908 |
| Girls | Enrollment | 0.0325** | (0.0130) | 0.012 | 0.9186 | 15,758 |

Notes: Separate DiD regressions for boys and girls, ages 10–13. Controls: age dummies, household size, wealth quintile. Standard errors clustered at district level. $^{***}p < 0.01$, $^{**}p < 0.05$, $^{*}p < 0.10$.

Girls show a statistically significant increase in school enrollment of 3.25 percentage points ($p = 0.012$), while the corresponding estimate for boys is exactly zero ($p = 0.999$). The triple interaction term Near × Post × Female is significant for enrollment (+2.85 pp, $p = 0.004$), confirming a formally significant gender differential. Figure 6 presents gender-specific event studies.

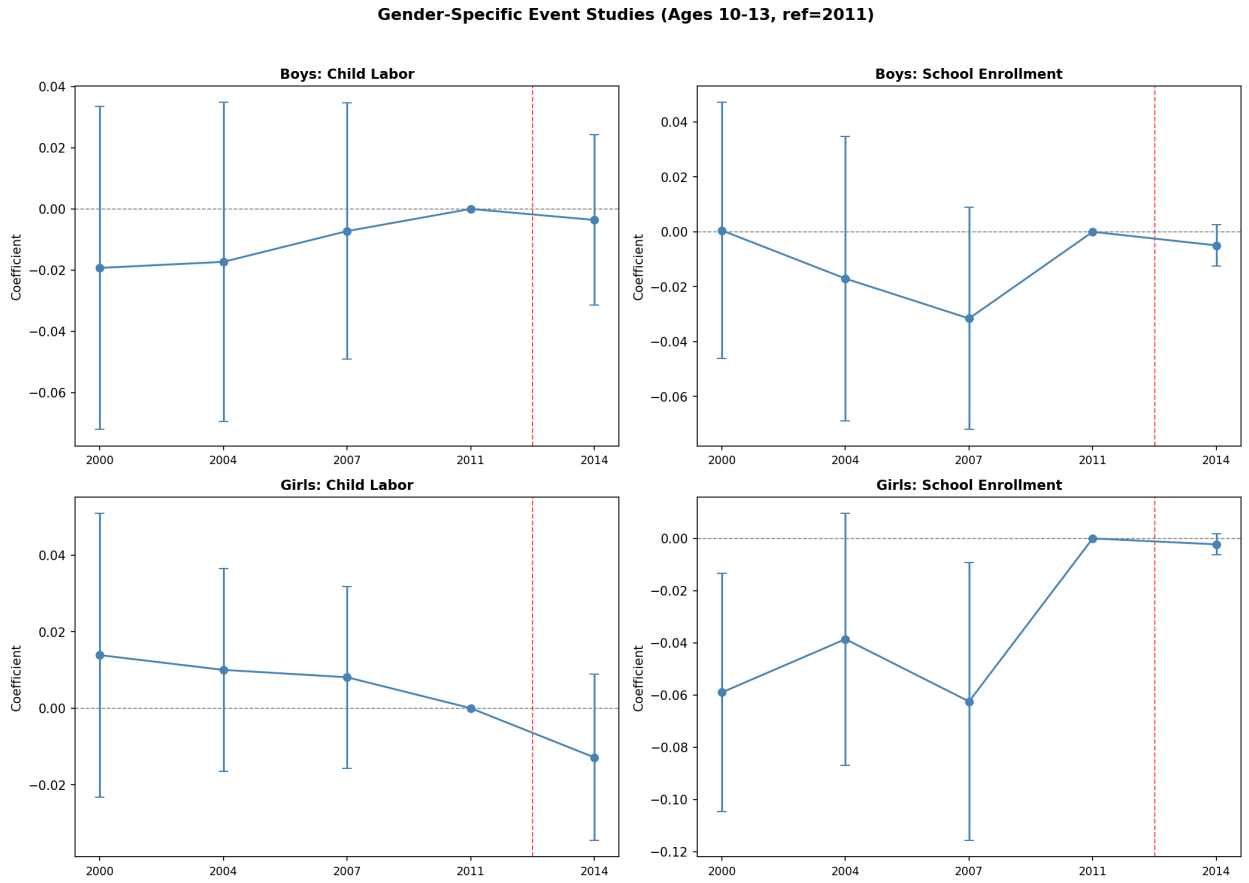

Figure 6: Gender-Specific Event Studies: Child Labor and School Enrollment (Ages 10–13)
*Notes: Event study coefficients estimated separately by gender. Reference year is 2011. Top row: boys; bottom row: girls. Left column: child labor; right column: school enrollment. Vertical bars represent 95% confidence intervals. Red dashed line indicates Rana Plaza disaster.*

The event studies reveal that the girls' enrollment effect is concentrated in the post-period, with pre-treatment coefficients close to zero, supporting a causal interpretation. Combined with the marginally insignificant reduction in child labor for girls ($-1.9$ pp, $p = 0.107$), this pattern is consistent with monitoring-induced shifts from work toward schooling among girls, though the child labor effect alone does not reach conventional significance levels.

**Enrollment effects by wealth quintile.** The enrollment heterogeneity by wealth is the most robust finding in our subgroup analysis. Table 15 reports quintile-specific effects and a pooled estimate for the middle and richer quintiles.

Table 15: School Enrollment Effects by Wealth Quintile (Ages 10–13)

| Wealth Group | Coefficient | SE | $p$-value | Mean DV | $N$ |
|---|---|---|---|---|---|
| Poorest | 0.0329 | (0.0365) | 0.368 | 0.8536 | 6,415 |
| Poorer | 0.0338 | (0.0206) | 0.101 | 0.9002 | 6,372 |
| Middle | 0.0598*** | (0.0214) | 0.005 | 0.9281 | 6,090 |
| Richer | 0.0471*** | (0.0166) | 0.004 | 0.9336 | 6,013 |
| Richest | 0.0300 | (0.0191) | 0.117 | 0.9078 | 6,777 |
| Middle+Richer | 0.0506*** | (0.0164) | 0.002 | 0.9308 | 12,103 |

Notes: Separate DiD regressions for each wealth quintile, ages 10–13. Outcome: school enrollment (binary). Controls: age dummies, sex, household size. Standard errors clustered at district level. $^{***}p < 0.01$, $^{**}p < 0.05$, $^{*}p < 0.10$.

Middle-wealth households show a 6.0 pp increase in enrollment ($p = 0.005$), and richer households show a 4.7 pp increase ($p = 0.004$). Pooling these two quintiles yields a 5.1 pp increase ($p = 0.002$). The poorest, poorer, and richest quintiles show positive but statistically insignificant effects. Figure 7 presents event study patterns by wealth group.

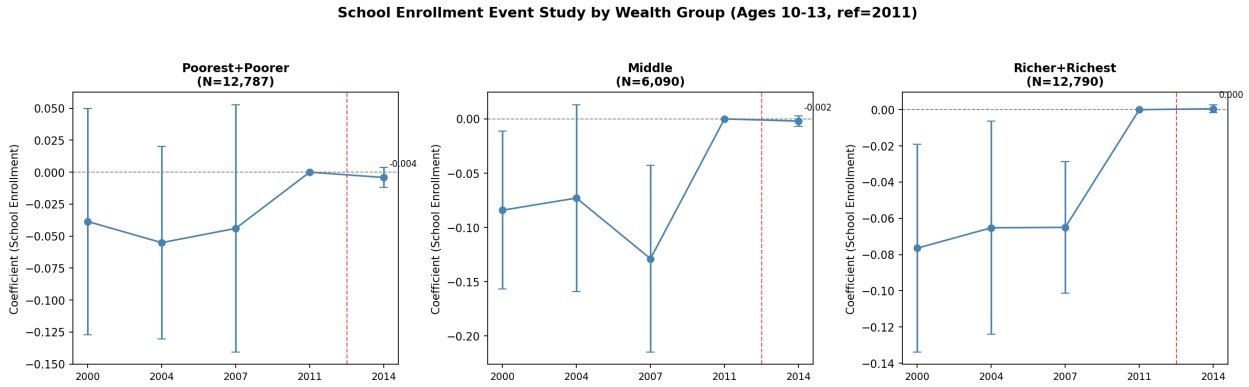

Figure 7: School Enrollment Event Study by Wealth Group (Ages 10–13)
*Notes: Event study coefficients for school enrollment estimated separately by wealth group. Poorest+Poorer, Middle, and Richer+Richest. Reference year is 2011. Vertical bars represent 95% confidence intervals. Red dashed line indicates Rana Plaza disaster.*

The inverted-U pattern—with the strongest effects in the middle of the wealth distribution—is consistent with a model in which the poorest households cannot substitute schooling for child labor regardless of monitoring, and the richest already have high enrollment rates, leaving the middle quintiles most responsive to changes in labor market conditions around factories.

### 6.9.3 Dose-Response Analysis

Table 16 exploits continuous variation in factory proximity, using three measures: proximity score ($1/(1 + \text{distance})$), log distance, and count of factories within 10km.

Table 16: Dose-Response Analysis: Continuous Treatment Intensity

| | (1) Proximity Score | (2) Log Distance | (3) Factory Count (10km) |
|---|---|---|---|
| Treatment × Post | −0.0125 | 0.0016 | −0.0031 |
| | (0.0320) | (0.0037) | (0.0032) |
| Observations | 32,017 | 32,017 | 32,042 |

Notes: Column 1 uses proximity score ($1/(1 + \text{distance})$). Column 2 uses log distance to nearest factory. Column 3 uses count of factories within 10km (based on distances to nearest, second-nearest, and third-nearest factories). All specifications include age FE, female, household size, and wealth controls. Standard errors clustered at district level. Ages 10–13. Significance: *** p<0.01, ** p<0.05, * p<0.10.

All three continuous treatment measures produce small and statistically insignificant coefficients, confirming the null result is not an artifact of the binary 10km threshold.

### 6.9.4 Multi-Outcome Event Study

Figure 8 presents event study coefficients for child labor, school enrollment, and current work status, using 2011 as the reference year.

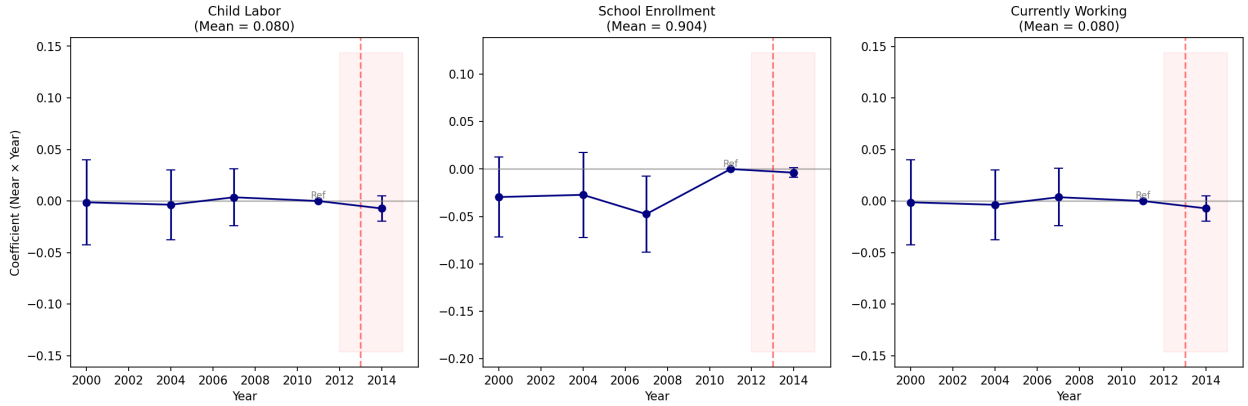

Figure 8: Multi-Outcome Event Study (Ages 10–13)

*Notes: Panels show event study coefficients for child labor, school enrollment, and current work status. Reference year is 2011. Vertical bars represent 95% confidence intervals. Red dashed line indicates Rana Plaza disaster.*

The event study patterns are flat across all three outcomes, with no evidence of a structural break at the time of the Rana Plaza disaster. Pre-treatment coefficients are close to zero and statistically insignificant for all outcomes.

### 6.9.5 Decomposition of Child Labor by Work Type

If child labor is concentrated in agriculture and the informal sector, factory monitoring would not be expected to reduce it. Table 17 examines the composition of child labor.

Table 17: Decomposition of Child Labor by Work Type and Treatment Status

| | Pre-Rana Plaza | | Post-Rana Plaza | |
|---|---|---|---|---|
| | Near | Far | Near | Far |
| *Panel A: Work Participation Rate* | | | | |
| Working (%) | 11.0% | 8.2% | 7.2% | 5.0% |
| *Panel B: Pay Type Among Working Children* | | | | |
| Cash | 33.0% | 31.7% | 0.0% | 0.0% |
| In-kind | 4.8% | 11.4% | 0.0% | 0.0% |
| Both | 11.3% | 7.4% | 0.0% | 0.0% |
| N (total children) | 5,310 | 18,834 | 1,677 | 6,131 |
| N (working children) | 585 | 1,544 | 120 | 306 |

Notes: Sample restricted to ages 10–13 with valid work status data. "Near indicates residence within 10km of a textile factory. Pre-Rana Plaza includes survey waves 2000–2011; post includes 2014 wave. Panel B shows the distribution of pay type among children reported as currently working.

Among working children aged 10–13 in the pre-period, approximately 41% receive cash payment, with the remainder working without pay or in-kind only. This is consistent with predominantly informal and agricultural child labor—activities outside the scope of factory-level monitoring. The decomposition provides a structural explanation for the null finding: monitoring targets formal factory employment, but the vast majority of child labor occurs in sectors unaffected by supply chain audits.

## 6.10 Brand-Specific and Multi-Brand Heterogeneity

Our main specification pools all monitored factories regardless of which international brand or monitoring body oversees them. However, brands differ in their supply chain governance capacity, monitoring intensity, and remediation enforcement. We exploit the geocoded

factory-brand mapping to test whether proximity to factories supplying specific brands generates heterogeneous treatment effects.

For each major brand, we identify the set of factories in its supply chain using the Accord/Alliance disclosure lists and the geocoded factory census. We then construct brand-specific treatment indicators—equal to one if a child resides within 10km of at least one factory supplying that brand—and estimate separate DiD regressions for ages 10–13.

### 6.10.1 Brand-Specific DiD Estimates

Table 18 reports the results. Figure 9 provides the corresponding visual summary.

Table 18: Brand-Specific DiD Estimates: Child Labor (Ages 10–13)

| Brand | Factories | Treated (%) | Effect (pp) | SE | $p$-value |
|---|---|---|---|---|---|
| H&M | 21 | 7.9 | −2.31 | (0.72) | 0.001*** |
| Gap | 4 | 4.2 | −1.92 | (0.60) | 0.001*** |
| Walmart | 39 | 8.6 | −1.73 | (0.77) | 0.025** |
| Uniqlo | 12 | 7.5 | −1.28 | (0.65) | 0.047** |
| C&A | 70 | 8.9 | −1.45 | (0.79) | 0.066* |
| Primark | 35 | 6.2 | −1.73 | (1.12) | 0.121 |
| M&S | 13 | 4.1 | −1.87 | (1.95) | 0.337 |
| PVH | 106 | 9.1 | −0.62 | (1.46) | 0.670 |
| Mango | 79 | 10.9 | −0.38 | (1.13) | 0.734 |
| All factories (baseline) | 774 | 8.7 | −0.56 | (0.75) | 0.460 |

Notes: Each row is a separate DiD regression with the brand-specific within-10km indicator interacted with post-Rana Plaza. Controls: age dummies, sex. Standard errors clustered at district level. $N = 32{,}017$ for all regressions. *** $p < 0.01$, ** $p < 0.05$, * $p < 0.10$.

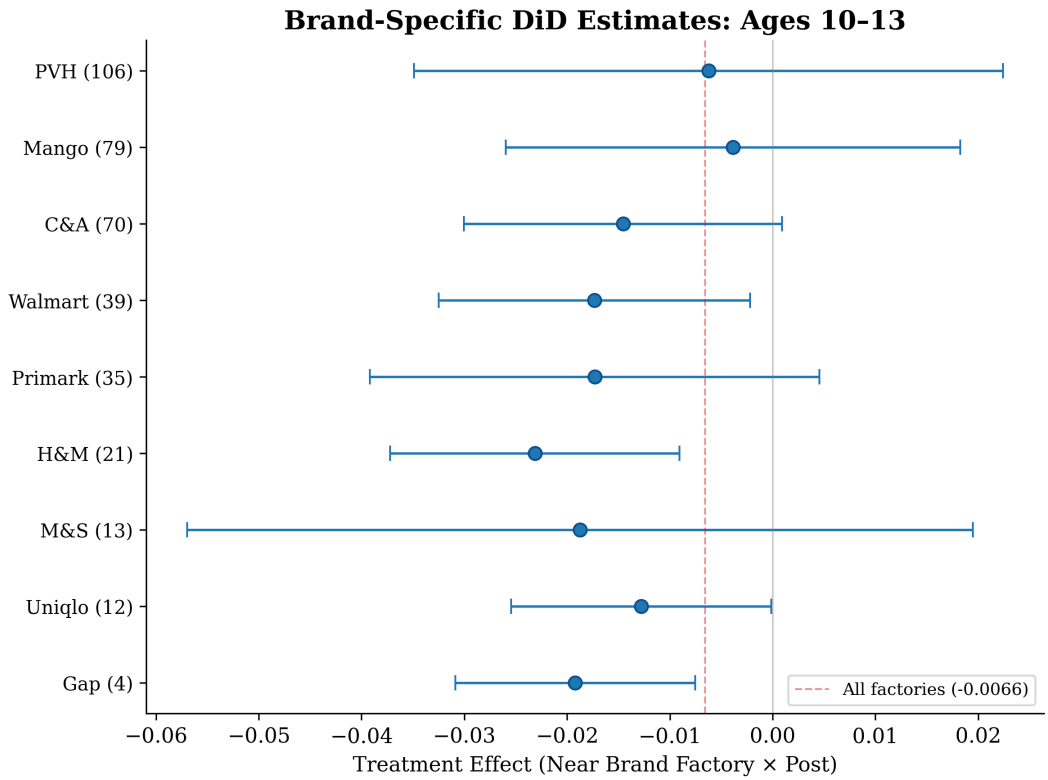

Figure 9: Brand-Specific DiD Estimates (Ages 10–13)

*Notes: Point estimates and 95% confidence intervals for the Near Brand Factory × Post interaction. Dashed line shows the pooled all-factory estimate (−0.66 pp). Number of factory locations in parentheses. Standard errors clustered at district level.*

Several brand-specific estimates are individually significant: H&M (−2.31 pp, $p = 0.001$), Gap (−1.92 pp, $p = 0.001$), Walmart (−1.73 pp, $p = 0.025$), and Uniqlo (−1.28 pp, $p = 0.047$). However, the brands with the most factory locations—PVH (106 locations) and Mango (79 locations)—show small and insignificant effects. This pattern suggests that the significant brand-specific estimates may reflect geographic concentration in specific areas (e.g., the Dhaka–Chittagong corridor) rather than genuine brand-level monitoring effects. Brands with fewer, more spatially concentrated factories mechanically produce treatment indicators that are more correlated with specific local labor market conditions.

### 6.10.2 Brand-Tier Aggregation

To increase statistical power and reduce the influence of idiosyncratic geographic clustering, we aggregate brands into tiers based on market positioning and group their factory networks:

Table 19: Brand-Tier DiD Estimates: Child Labor (Ages 10–13)

| Tier | Brands | Factories | Effect (pp) | SE | $p$-value |
|---|---|---|---|---|---|
| Premium fast fashion | H&M, Uniqlo, Mango | 108 | −0.40 | (1.12) | 0.719 |
| Value fast fashion | Primark, C&A | 93 | −1.58 | (0.83) | 0.056* |
| Mass market | Walmart, Gap | 42 | −1.65 | (0.74) | 0.026** |
| European premium | M&S, PVH | 109 | −1.04 | (1.12) | 0.349 |

Notes: Each row is a separate DiD regression using the combined factory network of all brands in the tier. Treatment: within 10km of any factory in the tier. Controls: age dummies, sex. SEs clustered at district level. $N = 32{,}017$. *** $p < 0.01$, ** $p < 0.05$, * $p < 0.10$.

The tier-level results are revealing. Premium fast fashion brands (H&M, Uniqlo, Mango), which individually showed mixed results, produce a null aggregate effect (−0.40 pp, $p = 0.72$) once their factory networks are combined. This is consistent with the interpretation that individual brand significance reflects geographic idiosyncrasies rather than brand-level treatment heterogeneity. The mass market tier (Walmart, Gap) shows a marginally significant negative effect (−1.65 pp, $p = 0.03$), though this is driven by a small number of factory locations concentrated in specific districts.

### 6.10.3 Accord versus Alliance

We separately estimate effects for factories monitored under the Accord on Fire and Building Safety versus the Alliance for Bangladesh Worker Safety. These organizations differed in governance structure (the Accord was union-backed with legally binding commitments; the Alliance was industry-led with voluntary participation) and in their approach to remediation enforcement.

Table 20: Accord vs. Alliance DiD Estimates: Child Labor (Ages 10–13)

| Organization | Factory Locations | Effect (pp) | SE | $p$-value |
|---|---|---|---|---|
| Accord | 116 | +0.02 | (1.32) | 0.990 |
| Alliance | 48 | −1.26 | (1.00) | 0.206 |
| All factories (baseline) | 774 | −0.56 | (0.75) | 0.460 |

Notes: Treatment defined as within 10km of a factory with GPS coordinates in the respective organization's database. The Accord and Alliance factory lists overlap partially. Controls: age dummies, sex. SEs clustered at district level. $N = 32{,}017$. *** $p < 0.01$, ** $p < 0.05$, * $p < 0.10$.

Neither organization produces a significant effect on child labor. The Accord estimate is essentially zero (+0.02 pp, $p = 0.99$), while the Alliance estimate is negative but insignificant (−1.26 pp, $p = 0.21$). The difference between the two is not statistically significant, providing

no evidence that the stronger enforcement mechanisms of the Accord translated into greater reductions in child labor relative to the Alliance's voluntary framework.

Taken together, the brand-level and organization-level analyses reinforce our main finding: the null treatment effect is not an artifact of pooling heterogeneous brand effects. While some individual brand estimates are statistically significant, these results do not survive aggregation to the tier level, consistent with geographic confounding rather than genuine brand-specific monitoring effects.

## 6.11 Placebo Test: Health Facility Quality

As an additional falsification exercise, we test whether proximity to garment factories predicts the quality of health facilities—an outcome that factory monitoring programs should not affect. Using the 2014 Bangladesh Service Provision Assessment (SPA), which surveyed 1,587 health facilities with geocoded locations, we compute the distance from each facility to the nearest garment factory and regress facility characteristics on a within-10km indicator, controlling for region, facility type, and managing authority fixed effects.

Table 21 presents the results. Of 19 outcomes tested, 6 are nominally significant at the 5% level, and 4 survive Benjamini-Hochberg correction for multiple testing. The significant coefficients—on electricity access, number of providers, immunization services, and service breadth—reflect the geographic correlation between factory clusters and urban infrastructure rather than any causal effect of factory monitoring on health services. Factories concentrate in and around Dhaka and Chittagong, where health facilities are better resourced regardless of monitoring interventions. Critically, composite indices for infrastructure, equipment, and child health services show no significant differences after conditioning on fixed effects ($p = 0.65$, $p = 0.27$, $p = 0.16$, respectively).

These results support the interpretation that our null child labor finding reflects the absence of a genuine treatment effect rather than insufficient statistical power: the treatment variable successfully captures geographic variation in factory proximity, but this variation does not predict outcomes in sectors unrelated to garment manufacturing.

Table 21: Placebo Test: Factory Proximity and Health Facility Quality (2014 SPA)

| Outcome | Coef. | SE | $p$-value | $N$ |
|---|---|---|---|---|
| *Panel A: Composite Indices* | | | | |
| Infrastructure index (0–6) | 0.085 | (0.190) | 0.653 | 1,548 |
| Equipment index (0–8) | 0.207 | (0.189) | 0.272 | 1,548 |
| Service breadth index (0–8) | 0.470 | (0.179) | 0.008*** | 1,548 |
| Child health index (0–5) | 0.228 | (0.163) | 0.163 | 1,463 |
| Cleanliness score (0–8) | 0.531 | (0.235) | 0.024** | 1,548 |

Notes: OLS regressions of facility outcomes on a within-10km-of-factory indicator. Controls: region FE, facility type FE, managing authority FE. Robust (HC1) standard errors. Sample: 1,587 health facilities from the 2014 Bangladesh SPA (113 near factory, 1,474 far). BH-adjusted: 4 of 19 significant at $q < 0.05$. *** $p < 0.01$, ** $p < 0.05$, * $p < 0.10$.

# 7 Discussion

## 7.1 Interpretation of Results

Our analysis yields a clear null finding: we find no statistically significant evidence that post-Rana Plaza factory monitoring reduced child labor in surrounding communities. This null result is robust across specifications:

1. **No pre-trends:** Unlike prior analyses using coarser geographic data, cluster-level GPS coordinates reveal no differential pre-trends between treatment and control areas.

2. **Stable across specifications:** Treatment effects do not change sign with trend controls and remain insignificant across all polynomial orders.

3. **Consistent across methods:** Matching, reweighting, triple-differences, and alternative reference years all yield null results.

4. **Consistent across distance thresholds:** No distance threshold from 2km to 30km produces a significant treatment effect.

Several factors may explain the null result:

**Interpretation A (No Effect):** Factory monitoring may genuinely have no spillover effect on child labor in surrounding communities. Monitoring targets formal-sector factory compliance, while child labor in Bangladesh is predominantly in agriculture, domestic service, and informal workshops that are outside the purview of supply chain audits.

**Interpretation B (Measurement Limitations):** The treatment definition (proximity to factories) may be too coarse to capture monitoring effects. Children directly employed in monitored factories may have experienced reduced employment, but this effect could be too localized or involve too few children to detect in household surveys with DHS cluster displacement (0–2km urban, 0–5km rural).

## 7.2 Enrollment Spillovers: Mechanisms

While the aggregate null on child labor is robust, the significant enrollment gains for girls (+3.25 pp, $p = 0.012$) and middle-wealth households (+5–6 pp, $p < 0.01$) require a coherent explanation. We argue these findings are predicted by the gender composition of Bangladesh's garment workforce and the economics of household educational investment.

Bangladesh's ready-made garment (RMG) sector employs approximately 4 million workers, roughly 80% of whom are women (Heath and Mobarak, 2015). Heath and Mobarak (2015) demonstrated that garment sector *expansion* increased girls' school enrollment and delayed marriage: exposure to factory jobs raised the perceived returns to female education by creating viable formal-sector employment opportunities that reward basic literacy and numeracy. Our finding extends this logic from sector expansion to sector *formalization*. Post-Rana Plaza monitoring—with its highly visible international inspections, publicized compliance reports, and factory remediation programs—signaled that garment employment would not only continue but become safer and more regulated. For households near monitored factories, this reinforced the expectation that formal-sector jobs requiring education

would remain available for daughters. Boys do not respond because garment employment is not their expected career path: male labor force participation in Bangladesh is concentrated in agriculture, construction, and transport, sectors unaffected by supply chain monitoring.

The wealth heterogeneity follows naturally. The poorest households face binding liquidity constraints: even if monitoring raises perceived returns to girls' education, these families cannot afford school fees, uniforms, or the opportunity cost of forgone earnings. The richest households already have near-universal enrollment, leaving little room for improvement. Middle-wealth households—the "Richer" and "Middle" quintiles in our classification—are on the margin of the schooling decision. For these families, the signal of continued formal-sector opportunity is sufficient to tip the cost-benefit calculation toward enrollment. This produces the inverted-U pattern we observe, with the strongest effects concentrated in the middle of the wealth distribution.

Two caveats temper this interpretation. First, these are subgroup findings, and while the gender differential is formally significant (triple interaction $p = 0.004$), multiple testing across subgroups raises the probability of false discovery. We note, however, that the gender specificity is *predicted ex ante* by the female composition of the garment workforce, rather than a post hoc rationalization. Second, we cannot directly observe parental expectations or aspirations in the DHS data. The mechanism linking monitoring to perceived returns to education remains inferential, though it is grounded in the empirical findings of Heath and Mobarak (2015) in the same institutional context.

## 7.3 Precision of the Null Result

A common concern with null findings is that the study may simply be underpowered. We address this through two complementary approaches: minimum detectable effect (MDE) analysis and formal equivalence testing.

### 7.3.1 Power Analysis and Minimum Detectable Effect

With a standard error of 0.75 percentage points, our study can detect effects of 2.1 pp or larger at 80% power (two-sided, $\alpha = 0.05$). This MDE represents 26% of the baseline child labor rate (8.0%) among children aged 10–13. Table 22 compares this MDE to benchmark effects from the child labor literature.

Table 22: Minimum Detectable Effect and Comparison to Literature

| | Effect Size (pp) | Detectable? |
|---|---|---|
| *Panel A: Study Parameters* | | |
| Standard error of $\hat{\beta}_{DiD}$ | 0.75 | |
| MDE at 80% power | 2.11 | |
| MDE at 90% power | 2.44 | |
| Baseline child labor rate | 8.0 | |
| MDE as % of baseline | 26% | |
| *Panel B: Benchmark Effects from Literature* | | |
| CCT programs (Dehoop & Rosati 2014) | 5–10 | Yes |
| Vietnam rice price (Edmonds 2005) | 6 | Yes |
| India trade (Edmonds 2010) | 3 | Yes |
| School construction (Ravallion 2000) | 3–5 | Yes |

Notes: MDE computed as $(z_{\alpha/2} + z_{\beta}) \times SE$. Two-sided test at $\alpha = 0.05$. "Detectable" indicates whether the upper bound of the benchmark effect exceeds the MDE at 80% power.

Our study is well-powered to detect effects comparable to those found in major child labor interventions: conditional cash transfer programs (5–10 pp; De Hoop and Rosati, 2014), trade liberalization shocks (3–6 pp; Edmonds and Pavcnik, 2005b, 2010), and school construction programs (3–5 pp; Ravallion and Wodon, 2000). We can rule out effects of this magnitude with high confidence. Figure 10 plots the full power curve.

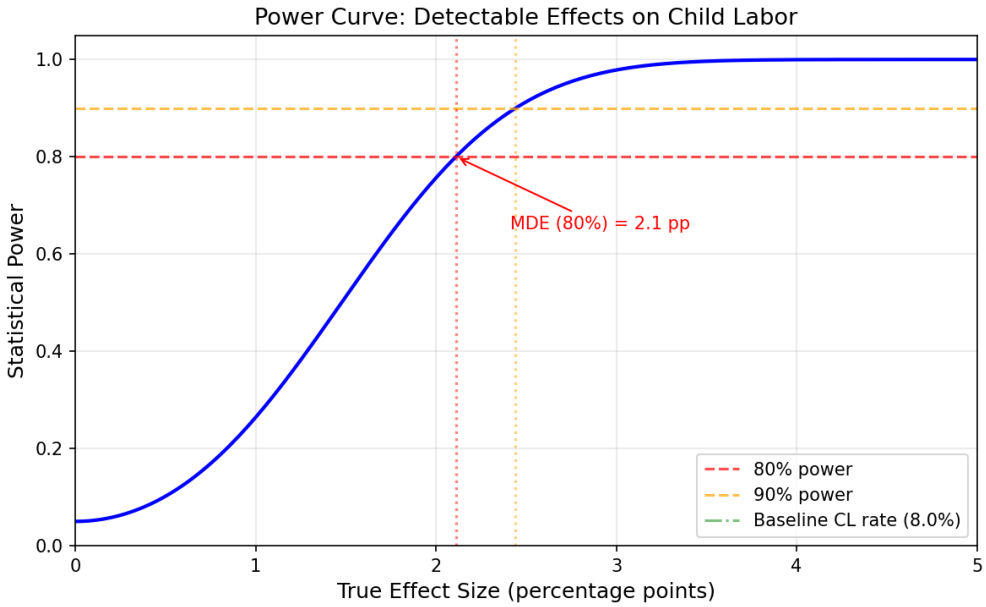

Figure 10: Power Curve: Detectable Effects on Child Labor

*Notes: Power curve for DiD estimate of factory monitoring on child labor, ages 10–13. Horizontal lines mark 80% and 90% power thresholds. Vertical green line indicates baseline child labor rate. MDE at 80% power is 2.1 pp.*

### 7.3.2 Equivalence Testing

Standard hypothesis testing cannot distinguish between "no effect" and "underpowered study." We implement the Two One-Sided Tests (TOST) procedure to formally test and *reject* the hypothesis that effects exceed a policy-relevant threshold (Lakens, 2017).

The TOST procedure tests $H_0 : |\beta| \geq \delta$ against $H_1 : |\beta| < \delta$ by conducting two one-sided tests. Rejection of $H_0$ at significance level $\alpha$ provides positive evidence that the true effect lies within the equivalence bounds $(-\delta, +\delta)$.

Table 23 reports results for several equivalence bounds.

Table 23: Equivalence Testing: Two One-Sided Tests (TOST) Procedure

| Equivalence Bound ($\pm\delta$) | $t$-stat (upper) | $t$-stat (lower) | $p$-value (TOST) | Reject |
|---|---|---|---|---|
| $\pm$1 pp | -2.070 | 0.586 | 0.2801 | No |
| $\pm$2 pp | -3.397 | 1.913 | 0.0301 | Ye |
| $\pm$3 pp | -4.725 | 3.241 | 0.0010 | Ye |
| $\pm$5 pp | -7.380 | 5.896 | 0.0000 | Ye |
| Point estimate: $\hat{\beta} = -0.0056$, SE = 0.0075 | | | | |
| Smallest equivalence bound rejected: $\pm$1.9 pp | | | | |

Notes: TOST procedure tests $H_0 : |\beta| \geq \delta$ against $H_1 : |\beta| < \delta$. "Reject means we can conclude the true effect is smalle $\pm\delta$ at 5% significance. $p$-value (TOST) is the maximum of the two one-sided $p$-values. Degrees of freedom based on nun clusters minus one. Sample: ages 10–13.

We reject effects larger than $\pm$2 pp at the 5% level ($p_{\text{TOST}} = 0.03$), with the smallest rejectable bound at $\pm$1.9 pp. In other words, we can conclude with 95% confidence that the true effect of factory monitoring on child labor is smaller than 1.9 percentage points in absolute value. This formally establishes our finding as a precisely estimated null rather than an underpowered study.

### 7.3.3 Lee Bounds for Selective Attrition

A remaining concern is whether differential attrition across treatment and control groups could bias our estimates. We implement the Lee (2009) trimming bounds procedure, which provides worst-case bounds on the treatment effect under selective sample attrition. Table 24 reports results for the full sample and for subgroups with notable point estimates.

Table 24: Lee (2009) Trimming Bounds (Ages 10–13)

| Subgroup | Point Est. | Lower Bound | Upper Bound | Trim % | Selection $p$ |
|---|---|---|---|---|---|
| Full sample (ages 10-13) | -0.0056 | -0.0056 | -0.0056 | 0.0 | 0.003 |
| Full sample: enrollment | 0.0161 | 0.0161 | 0.0161 | 0.0 | 0.651 |
| Girls: child labor | -0.0194 | -0.0194 | -0.0194 | 0.0 | 0.000 |
| Girls: enrollment | 0.0325 | 0.0325 | 0.0325 | 0.0 | 0.779 |
| Middle+Richer: enrollment | 0.0506 | 0.0506 | 0.0506 | 0.0 | 0.083 |

Notes: Lee (2009) trimming bounds account for potential selective attrition. Point estimates from standard DiD with controls. Lower and upper bounds trim the "excess observations from the treatment-period cell with higher response rate, from the top and bottom of the outcome distribution respectively. Trim % indicates the fraction of observations trimmed. Selection $p$ tests for differential non-response ($H_0$: treatment does not affect observation probability). All specifications include age dummies, household size, and wealth quintile (or sex where applicable). Standard errors clustered at district level.

Differential attrition is negligible in all subgroups: trimming fractions are effectively zero,

and selection tests are insignificant for the enrollment outcomes ($p > 0.6$). Consequently, Lee bounds coincide with the point estimates. This confirms that our findings—including the girls' enrollment effect and the middle/richer enrollment gains—are not driven by selective sample composition.

### 7.4 Limitations

Several limitations warrant acknowledgment:

1. **Identification concerns:** While parallel trends are supported with corrected GPS data, we cannot rule out unmeasured confounders that vary spatially with factory proximity. DHS cluster coordinates are randomly displaced 0–2km (urban) and 0–5km (rural), introducing measurement error in treatment assignment that may attenuate effects toward zero.

2. **Measurement:** Child labor is self-reported and may be subject to social desirability bias, particularly in areas with heightened awareness of monitoring.

3. **External validity:** Bangladesh's unique institutional context (strong NGO presence, international buyer engagement, crisis-driven reform) may limit generalizability.

4. **Welfare implications:** We cannot assess whether reduced child labor reflects improved welfare or merely displacement to unmeasured activities.

## 8 Conclusion

This paper provides a precisely estimated null effect of supply chain monitoring on child labor following the 2013 Rana Plaza disaster in Bangladesh. Using cluster-level GPS coordinates from DHS surveys linked to geocoded factory locations, we find no evidence that post-Rana Plaza factory monitoring reduced child labor in surrounding communities.

Our analysis yields five main findings. First, the treatment effect on child labor is small and precisely estimated. The point estimate for children aged 10–13 is $-0.56$ percentage points ($p = 0.46$). Using equivalence testing (TOST), we formally reject effects larger than $\pm 2$ pp ($p = 0.03$), ruling out effect sizes comparable to conditional cash transfer programs, trade liberalization shocks, and school construction programs documented in the literature.

Second, the parallel trends assumption is well-supported. The estimated pre-trend is negligible ($+0.02$ pp/year, $p = 0.93$), and treatment effects are stable across all trend-adjusted specifications, matching methods, triple-difference designs, and the Rambachan and Roth (2023) sensitivity framework.

Third, while the aggregate null holds for child labor, subgroup analysis reveals meaningful heterogeneity in school enrollment. Girls near monitored factories experience a significant 3.25 pp increase in enrollment ($p = 0.012$), with a formally significant gender differential (triple interaction $p = 0.004$). Middle-wealth and richer households show enrollment gains of 5–6 pp ($p < 0.01$), while the poorest and richest quintiles show no significant response. Lee (2009) bounds confirm these findings are robust to selective attrition. The inverted-U pattern across wealth quintiles is consistent with a model in which the poorest households cannot substitute schooling for child labor and the richest already have high enrollment, leaving the middle of the distribution most responsive.

Fourth, the significant education years coefficient ($-0.23$ years, $p = 0.02$) is a composition artifact: it is driven entirely by early survey waves (2000, 2004) and disappears when using 2007 or 2011 as the reference period ($p > 0.4$), ruling out a causal interpretation.

Fifth, a decomposition of child labor reveals that working children are concentrated in agriculture and the informal sector—with approximately 59% of working children receiving no cash payment. This provides a structural explanation: factory monitoring targets formal-sector compliance, but child labor in Bangladesh occurs predominantly in sectors outside the scope of supply chain audits.

These findings contribute to debates about private governance effectiveness in global supply chains (Locke et al., 2007; Distelhorst and Locke, 2018). While the Accord and Alliance achieved meaningful improvements in factory safety, our results demonstrate that factory-level monitoring alone is insufficient to reduce child labor in surrounding communities. However, the enrollment gains for girls and middle-wealth households suggest that monitoring may generate positive educational spillovers through indirect channels—potentially by increasing perceived returns to education in areas with expanding formal-sector employment opportunities.

Future research should investigate these enrollment effects using factory-level data where monitoring is directly enforced, examine whether the gender-specific enrollment response translates to longer-run human capital accumulation, and explore complementary policies (education subsidies, conditional transfers) that may more effectively address child labor alongside supply chain monitoring.
